NORMAN REEF ENVIRONMENTAL MONITORING PROJECT 1987-88

Sea Research: A.M. and A.L. Ayling

April 1989

SUMMARY

The establishment of a tourist destination pontoon serviced by 300 seat international catamarans on Norman Reef to the NE of Cairns prompted the GBRMPA to require an on-going biological monitoring program to be implemented. The aims of the program were to attempt to establish the effect such intensive tourist operations were having on the reef community; specifically on the percentage cover of encrusting organisms, the height of coral colonies and the density of selected fish species.

Surveys of corals, other encrusting organisms and fishes were made at 4 sites on Norman Reef between March 1987 and June 1988. Sites were: adjacent to the Great Adventures pontoon; in the area of Great Adventures semi-submersible operation; adjacent to the Deep Sea Divers Den main mooring; and at an undisturbed control area. A total of 35 permanent 20m line transects were used to measure the cover of corals and other encrusting organisms. Measures of coral height were also made at each site. Fishes were counted along 5 haphazard 50 x 20m transects at each site.

Corals were only affected directly by the pontoon, either by shading or mooring chain abrasion. This affected an area of about 365 square metres of potential coral habitat (hard substratum beneath the pontoon), and resulted in the loss of 32 square metres of live hard coral (a 4.3% reduction against the 4.6% increase in both control sites). As a result coral height was significantly reduced at this site, but the mean height reduction per coral colony was only 6.4cm.

Diver activities did not have any detectable effect either on coral cover or coral height at any of the potentially affected sites in the time scale of this survey.

This survey indicated that operating semi-submersibles occasionally touch the reef; there was a 2m long gouge in the coral basement across one of the semi-sub transects, and an approximately 50cm high knob of coral missing from the end of another, that were both almost certainly the result of semi-sub bumps. However, both these observed incidents resulted in negligible coral damage and there were no significant reductions either in coral cover or coral heights in the semi-sub transects.

There were no significant effects detected on the abundance of any of the other groups of encrusting organisms, including macroalgae, turfing algae, sponges and soft corals.

Fish were obviously affected by tourist activities with small numbers of several species attracted to the activity sites, especially the pontoon site. In the final survey there were moderately high numbers of 6 species in the immediate vicinity of the pontoon that were either absent or uncommon at the other 2 sites, probably due to the daily fish feeding activities made from the pontoon. There were no detectable reductions in any of the species counted, although there were indications that chaetodontids had decreased in numbers immediately beneath the pontoon, probably as a result of the reduction in coral cover.

With the exception of a few small patches immediately beneath the pontoon there were no deleterious effects on aesthetics in the reef communities of the survey sites during the 12 months of this survey. Norman Reef is aesthetically very spectacular, mainly

as a result of rich coral communities and consistently clear water. Any degradation of the coral communities would have a noticeable effect on aesthetics but this has not occurred to date

It is recommended the the Norman Reef monitoring program be continued and expanded because of increased use of the reef by tourist operators and to establish the longer term effects of such intensive albeit non-exploitative use.

INTRODUCTION

Norman Reef (16° 52'S; 146°E) is a small oval shaped reef that lies approximately 60km north of the city of Cairns on the southern edge of Trinity Opening (figure 1). With a cross-shelf position of 0.85, Norman can be regarded as an outer shelf reef, and is one of the few reefs zoned General Use A. The combination of its small size (1.5 x 2.5km; see figure 2), outer shelf position and isolation (Norman is at least 10km from other large reefs) means that this reef is usually bathed in clear oceanic water with underwater visibility of between 15 and 30m.

This reef is one of the few in the Cairns area that was not subject to extensive coral damage in the crown of thorns outbreak of the early 1980s. The rich coral communities, clear water and proximity to Cairns began to attract the attention of the expanding tourist dive industry in Cairns in the mid 1980s. The Deep Sea Divers Den (DSDD), a diver training school based in Cairns, began running their catamaran 'Tropic Queen' to Norman in March 1986 with up to 26 trainee divers. Since then this boat has made 3 two day trips each week to Norman Reef resulting in approximately 600 dives in the area per week, the majority in the vicinity of the new DSDD mooring.

Late in 1986 the Hayles tourist boat operating company (now called Great Adventures) became interested in establishing a fast catamaran day trip tourist operation to a destination pontoon on Norman Reef. There was some opposition from the DSDD, but after discussions by both parties with the Marine Parks in Cairns it was agreed that DSDD would move to a new site SW of their existing mooring, leaving Hayles to use the more appropriate centre area of the back reef bay. Hayles were given permission for this operation by the GBRMPA in early 1987 and began establishing moorings for the pontoon on 1st April 1987 using heavy chain and large concrete blocks.

The 45 x 15m pontoon was put in position in the vicinity of the old DSDD mooring in May 1987 and operations began using a single 30m International Catamaran immediately afterward, with the capability of transporting up to 300 persons to the reef every day. In addition to the destination pontoon, that acts as a base for swimming and snorkeling activities as well as providing more space for the visitors to move around, Hayles uses 2 glass bottomed boats and 2 semi-submersible coral viewers (semi-subs) to give non-swimmers a view of the reef community. Regular fish feeding is carried out from the pontoon using food scraps to provide a spectacle for the tourists.

The purpose of this survey was to check whether the presence and operation of the pontoon and associated tourist activities including fish feeding, or the diver activity and the associated limited, irregular fish feeding at the DSDD site were having any effect on the reef community. As there has been concern about the effects of semi-submersible operation on corals along the shallow reef edge where these vessels run, the monitoring survey was also designed to check on the extent of this damage.

METHODS

STUDY SITES

Four sites were chosen, all of them on the sheltered back reef region that was and is the focus of tourist activity (see figure 3).

The first was in the immediate vicinity of the Hayles (now Great Adventures) reef destination pontoon (see figure 4). Swimmers and snorkelers at the pontoon are restricted by buoyed lines to the area east and south of the pontoon to avoid conflict with the semi-sub and glass bottomed boat operation. The majority of swimmers and snorkel divers do not venture more than 100m from the pontoon. The deep transects were positioned either immediately beneath the indicated position of the pontoon or within an estimated 20m of the pontoon edge. The shallow transects at this site were set up around the edges of the patches of reef flat closest to the pontoon position; it was reasoned that these would receive the greatest level of snorkeler/swimmer impact. The semi-sub and glass bottom boat moorings at the Pontoon site were in deeper water some distance out from the pontoon over a predominantly sand bottom; no detrimental effects were expected from these moorings.

Site 2 was in the area of the permanent mooring used by the Deep Sea Divers Den boats "Tropic Queen" and "Tropic Princess" for their diver training operations and covered an area approximately 200m square (see figure 5). The permanent transects at this site were set up about a month after the DSDD had shifted their mooring to the new site and were confined to the area that observation and consultation suggested was the most intensively used by the trainee divers.

The third site was a control about 200m wide mid-way between the first two sites that was out of bounds to both operations (see figure 6).

Site 4 incorporated the area to the north of the pontoon that was used by the two semi-submersibles operating from the pontoon (see figure 7). As at the DSDD site the transects at this site were set up about a month after operations had started to ensure that they were immediately adjacent to the semi-sub route that was being used in practice rather than that proposed before operations began.

CORAL TRANSECTS

Encrusting organisms were assessed using permanent 20m line intersect transects. Transects were marked with 100mm masonry nails driven into the coral basement or massive corals at intervals of 2-4m. The length of intersection of all encrusting organisms with the transect line was recorded in cm - the sum of these intersects giving a measure of percentage cover for the various species. Five replicate transects were positioned haphazardly in each of two depth strata at each site. The five shallow transects were between 0-2m below mean low water (MLW), while the deep transects were between 6-10m below MLW. No deep transects were surveyed at the semi-sub site. Differences in the cover of encrusting organisms between sites and depths were tested using a two factor analysis of variance, while changes through time, being non-independent, were tested using a t-test for the comparison of the means of paired samples. As 101 separate t-tests were necessary for this analysis the level of probability taken as significant was 99% rather than the normal 95%.

CORAL HEIGHTS

One of the concerns about heavy tourist use of a coral reef area is that snorkelers and divers may inadvertently break portions off erect and branching corals and eventually cause significant degradation to the area around a regularly used destination. Similarly it has been thought that regular bumping of reef edges by semi-submersibles trying to get as close as possible to the coral may cause additional damage to corals. In an attempt to quantify this type of damage measurements of the maximum height of branching and plate type corals were made along each of the permanent transects. The highest piece or clump of live coral in a square metre centred on each metre of the transect line was measured, giving 20 height measurements for each transect. If there was no erect hard coral within this square metre the piece nearest to the line outside this area was measured. Changes in coral height were tested using a t-test for the comparison of the means of paired samples.

FISH COUNTS

Selected groups of fishes were counted along five haphazard 50 x 20m transects at three of the sites; no fish counts were made at the semi-sub site. Each count was marked using a 50m central fiberglass tape run out at a depth of about 5-8m and fish counted 10m each side of the line. Fish counted were those that experience suggested could be affected by the fish feeding and other tourist activities and included: large non-secretive cods and coral trout (family - Serranidae); jacks and trevallies (Carangidae); snappers or sea-perch (Lutjanidae); fusiliers (Caesionidae); sweetlips (Haemulidae); emperors (Lethrinidae); batfishes (Ephippidae); butterflyfishes (Chaetodontidae); large wrasses (Labridae); parrotfishes (Scaridae); surgeonfishes (Acanthuridae); and rabbitfishes (Siganidae). As both sets of fish counts were made using haphazard and hence independent samples a two factor analysis of variance was used to test for differences among sites and between times.

RESOURCE MAPPING

The area around the tourist destination pontoon was mapped in detail using aerial photographs and the position of all large massive corals, large coral clumps and giant clams plotted. It was anticipated that this map would be of use to the operators as an aid to help tourists understand what they were seeing while investigating the reef community. It would also provide a baseline for looking at the long term effect of tourist activities on the larger coral colonies and giant clams.

SAMPLING DATES

A special trip to the study area was made at the end of March 1987 to survey the Pontoon Site prior to the establishment of the pontoon moorings: the 10 encrusting organism transects were set up and surveyed at this time, along with the first group of fish counts. The remainder of the initial survey of all sites, including the resource map, was made during the period June-July 1987. The final survey at all sites was made in June 1988.

RESULTS

CORAL COVER

Raw data and preliminary analyses for all the groups of encrusting organisms recorded in the permanent transects are included in appendix 1 and summarised in table 1.

Norman Reef has a very rich cover of hard coral compared with most other outer shelf or mid-shelf reefs on the GBR. Coral cover at the start of the survey ranged from 45.1-53.1% for the shallow sites, and from 43.4-61.1% for the deep sites. For comparison, mean coral cover measured on the back reef of 9 Central Section outer shelf reefs measured using ten 10m line intersect transects was 27.7% (range from 21.2-35.2%), while coral cover on 19 mid-shelf reefs unaffected by *Acanthaster* grazing in the same area was 26.7% (range from 15.2-48.8%) (data from Ayling and Ayling, 1985). Similarly, mean coral cover on 38 Capricorn Section reefs was 22.6% (Data from Ayling and Ayling, 1986).

Initially (1987 survey) there was no significant difference in coral cover, either between sites or between depths. However, the composition of the coral community was different between the two depth strata. In the shallow transects plate acroporids (10% cover) and small clumping acroporids (12%) were the major components of the coral community, along with poritids (11%), pocilloporids (2.5%) and faviids (4.8%). In contrast poritids were strongly dominant in deeper water (34% cover), faviids were similar to shallow areas (4.3%), while small clumping acroporids (6%), plate acroporids (0.1%) and pocilloporids (1%) were markedly less abundant than in the shallow transects (see table 2).

In overall hard coral cover there were increases in several groups of counts over the time of the survey but this was only significant at the semi-sub shallow site where the percentage cover of corals increased from 53 to almost 64. A significant increase in plate acroporids was the main component of this change (see table 2). The only real reduction, although non-significant, was recorded at the deep pontoon site where shading killed some corals and damage from moorings and chain abraded others, resulting in a drop from 61 to 57% cover.. This was reflected in non-significant reductions in the cover of poritids, staghorn acroporids and small clumping acroporids.

CORAL HEIGHTS

The measure of coral height indicated a slight but non-significant increase in height at both DSDD sites (see table 3), and a strongly significant decrease at the deep pontoon site. This decrease was caused by the shading death of some large staghorn corals beneath the pontoon and damage to some branching corals by the moorings and chain.

OTHER ENCRUSTING ORGANISMS

There were no significant changes in the cover of soft corals, macroalgae, turfing algae or sponges at any of the sites, although there was a decrease in macroalgae on the shallow pontoon site, and an increase in turfing algae at both DSDD sites and the deep control site (see table 1).

FISHES

Raw data from all fish counts, along with preliminary analyses, are tabulated in appendix 2. Abundance summaries and the results of 2 factor analyses of variance for the totals for the common families are shown in table 4.

Observation showed that some groups and species of fishes gathered at the sites of tourist activity, most of them attracted by the feeding. At the DSDD site fish feeding activities were irregular and involved throwing over of a few food scraps after meals and some feeding of scraps to fish by the divers while underwater. As a result there were usually a few schools of fusiliers present in the vicinity of the moored boat, while 2-10 individuals of the species *Platax orbicularis* (batfish), *Lethrinus nebulosus* (spangled emperor) and *Hipposcarus longiceps* (yellow-tailed parrotfish) were attracted to the site when divers were in the water. Beneath the pontoon there were also schools of fusiliers, as well as large schools of *Lutjanus bohar* (red bass) and *L. gibbus* (paddle-tails). There were also a few spangled emperors, some parrotfishes, and one or two medium sized cod and coral trout at this site at the end of the survey period.

There were strong site effects for scarids, with high numbers at the pontoon site for all surveys compared with the other two sites. This was a result of the features of the site itself rather than the presence of the pontoon; there were high numbers here before the pontoon was installed and no significant time effects. Numbers of fusiliers were very variable with standard deviations mostly considerably greater than the mean, and although there was a numerical increase in density both at the pontoon site and the DSDD site this was not significant. There was a significant site effect for fusiliers: densities at the pontoon site and DSDD site were higher than at the control site in the second survey. Lutjanids showed a dramatic and significant increase in density at the pontoon site with large resting schools of *Lutjanus bohar* and *L. gibbus* beneath the pontoon in the June 1988 survey, along with small numbers of *L. fulvus* (blacktail snapper) This also gave a significant site effect.

DISCUSSION

CORAL COVER

If the tourist activities at the pontoon site and the DSDD site were having any detrimental effect on hard coral communities then a reduction in coral cover at either of these sites in comparison with the control site would be expected. In fact, there was an increase of 5.6 percentage points in coral cover at both control sites that was significant at the 95% probability level but not at the 99% level accepted here. There were similar or larger increases in coral cover at the DSDD deep site, the shallow pontoon site and the semi-sub site - the latter significant at the 99% level. Given the cover of fast growing acroporid corals at these sites, ranging from 20-45% in the shallow sites, this sort of increase in cover is to be expected over a 12 month period as a result of colony growth alone.

There was only a very slight increase in coral cover at the DSDD shallow site, possibly a result of the relatively low cover of fast growing acroporids at this site: 18.8% compared to 27.3%, 27.5% and 44.5% at the other 3 shallow sites. In contrast there was a 4.3 percentage point reduction in coral cover at the deep pontoon site due to the death from shading of most acroporids and some poritids and other species beneath the pontoon. Over the first few months the shaded corals changed colour to a dark brown in an attempt to cope with the reduced light levels. Many corals subsequently died but others have been able to survive under the new low-light regime. Other corals in the vicinity of the pontoon were damaged or destroyed by mooring chain abrasion. There was, however, no reduction in coral cover in the shallow pontoon site, despite being exposed to potential damage from large numbers of inexperienced snorkel divers every day. Such use may be expected to cause coral damage in shallow water from careless swim fin kicking or by snorkelers standing on the reef to rest or clear their mask, but any such effect is not great enough to reduce live coral cover over the period of this study.

The fast growing acroporid corals increased in cover over the period of this study at all sites with the exception of the shaded deep pontoon site where a 17% reduction in total acroporid cover was recorded (from data in table 2). The mean increase in cover of these corals at the other 6 sites was 21.6% (range from +12.7% to +28.4%) The combined cover of all other groups of hard corals, mainly poritids, faviids and pocilloporids, did not show the same consistent change, with a mean increase recorded of only 4.7% (range from -5.1% to +14.1%). Like the acroporids these other corals also showed a reduction at the deep pontoon site where a change of -5.3% was recorded.

Snorkel diver activities and similar scuba diver effects may also be expected to reduce the average height of erect, branching and plate forming corals, even if it does not reduce live coral cover. Similarly if the semi-sub activities along the reef edge to the north of the pontoon were occasionally breaking erect or plate forming corals this might be expected to reduce coral height. The coral height measurements made along each of the permanent coral transects did in fact show up a significant reduction in coral height in the deep pontoon site due to the death from shading of branching acroporids beneath the pontoon and the breakage and destruction of some erect corals in this area by the pontoon mooring chains. Although this demonstrated the sensitivity of this method to overall changes in coral height, no reductions in coral heights were detected at any of the other sites.

OTHER ENCRUSTING ORGANISMS

Soft corals were not abundant in this region of Norman Reef, ranging from 4-10% cover at the majority of sites. These populations were very stable through time with a maximum change of 1% in cover over 12 months.

Any nutrient enrichment resulting from the tourist activities in this area may be expected to lead to an increase in the cover of macro- or turfing algae. In fact, although there was an increase in turf cover at both DSDD sites and the deep control site and a decrease in macroalgal cover at the shallow pontoon site, there were no significant changes at any site. Mean macroalgal cover ranged from 0.2-2.0% at the beginning of the survey period and from 0.2-2.1% 12 months later. Similarly, turfing algae ranged from 0-1.9% initially and from 0-3.3% 12 months later.

It has been postulated that sponges respond to any organic pollution by increasing in abundance (Wilkinson, 1987). Sponges were not common in this region of Norman Reef ranging from 0-2.8% cover - there were no significant changes over the period of the survey.

FISHES

Most of the obvious changes in the reef community around heavily used tourist destinations are in fish populations. Many reef fishes are opportunistic and quickly gather at sites of disturbance or feeding, while others may be repelled by the constant tourist activity. There is anecdotal evidence that chaetodontids (butterflyfishes) decrease in density at areas of heavy diver activity (Wendy Richards, personal communication re Agincourt Reef pontoons), but this may be due to reductions in coral cover and/or quality as many of these fishes are obligate coral feeders.

The initial survey in late March 1987 was not completed prior to all tourist activity. The Deep Sea Divers Den had been using a permanent mooring (a chain wrapped around a small coral knob) at the pontoon site for their boat 'Tropic Queen' for about 12 months prior to this initial survey. The divers had been feeding large fishes, including *Lethrinus nebulosus*, *Platax orbicularis* and *Cheilinus undulatus* (maori wrasse), and relatively small numbers of these species had been attracted to this site. As a result total lutjanids, lethrinids and ehippids were slightly higher at the pontoon site than at the other two sites prior to the establishment of the pontoon.

As has been mentioned, the main fish species attracted to diver activities were *Platax orbicularis*, *Lethrinus nebulosus*, *Cheilinus undulatus*, *Caesio cuning* (fusilier) and *Hipposcarus longiceps*. These species were present at the pontoon and DSDD sites during the final survey, all except *Caesio cuning* in relatively small numbers, but did not increase significantly over the period of the survey. The most obvious fish effect was the large school of about 200 *Lutjanus bohar* and *L. gibbus* adjacent to the pontoon during the final survey. This resulted in a significant time effect on the density of the family Lutjanidae due to an order of magnitude increase from an initial mean of 5.4 per 1000 square metres to a final mean of 51.6.

There was also an order of magnitude significant increase in the surgeon fishes *Acanthurus xanthopterus* and *Naso brevirostris* in the immediate vicinity of the pontoon, but this was due to the presence of schools containing only 23 and 16 individuals respectively. There was a slight decrease in the density of butterfly fishes (chaetodontids) at the pontoon site over the 12 month survey period, especially immediately beneath the pontoon where only 3 individuals were recorded during the final survey. However, there were similar slight falls in the other 2 sites; these decreases were not significant overall.

MANAGEMENT IMPLICATIONS

All evidence to date suggests that the level of use of Norman Reef by tourist and dive operators between April 1987 and July 1988 was not having any significant widespread detrimental effect on the reef community. The only effects on encrusting communities detected during this survey have been due to the hardware installation at the pontoon site. There was a non-significant reduction in coral cover and a significant decrease in coral height at the deep pontoon site attributable to shading induced coral death and mooring chain abrasion. No effects on encrusting communities or coral heights that can be directly attributable to the activities of swimmers, snorkel divers or scuba divers have been observed.

Some fish species have been attracted to the vicinity of the pontoon installation by fish feeding activities, causing a significant increase in the density of lutjanids (snappers and sea perch) and 2 species of surgeonfishes at this site. However, these are fishes that normally occur in resting or feeding schools on the reef and no unusual effects can be expected from the gathering generated by the pontoon. There were naturally occurring larger schools of these and a number of other similar species observed on several dives during both surveys on the large bommie 450m to the NNE of the pontoon site where one of the semi-sub transects was located (see map figure 7).

Since this survey was initiated, the use of Norman Reef by dive charter boats has increased markedly. The Deep Sea Divers Den now have a second boat and mooring SW of the DSDD site that was part of this survey. In addition about 5 other boats occasionally anchor or moor along the face of the reef between the pontoon and the northern end of the reef.

In view of the increasing use of the 2.5 km long back edge of this reef it is suggested that a further 3 monitoring sites be established to cover these new centres of activity, and provide additional control sites. This would include an expansion of the semi-sub site to include both a deep coral site and fish counts, and bring the total number of sites to 6. The position of additional sites would be determined by means of a user survey carried out in conjunction with Marine Parks: one site would be in the area most heavily used by transient boats and the other in the least used back reef area as an additional control.

Survey methods used would be basically the same as those used for this survey but would be expanded in some areas. Broken but still living coral would be scored at all sites, probably during a 30 minute haphazard search of the entire site area. This would give another measure of the coral damage caused by diver activity that may in the long term lead to aesthetic degradation while not causing any significant decrease in coral cover. A number of photos taken annually from fixed points of a fixed scene will also be set up to look at aesthetic changes in the long term. Estimates of the area in square metres showing damage caused by anchoring activities would be recorded in the 50 x 20m transects used for fish counts to get a more widespread picture of the effect on the coral community of boat anchoring. Surveys at 12 month intervals of the new and previously established sites should be sufficient in view of the results from this study.

APPENDIX 1

RAW DATA FROM THE SURVEYS OF HARD CORALS AND OTHER ENCRUSTING ORGANISMS MADE IN THE FOUR MONITORING SITES ON NORMAN REEF

Raw data from the 5 replicate permanent transects is shown as total intercepts in cm for each species or group of species, along with the mean and standard deviation for each group of transects (bold type). See figures 4-7 for the position of the transects.

Transect #	1 (cm)	2 (cm)	3 (cm)	4 (cm)	5 (cm)	mean (% cover)	std.dev. (% cover)

APPENDIX 2

RAW DATA FROM THE SURVEYS OF SELECTED FISHES MADE IN THREE OF THE MONITORING SITES ON NORMAN REEF

Raw data from the 5 replicate transects is shown along with the mean and standard deviation for each group of transects (bold type). See figures 4-6 for the areas within which the transects were haphazardly surveyed.

SUMMARY:
